Cytophagic histiocytic panniculitis, hemophagocytic lymphohistiocytosis and undetermined autoimmune disorder: reconciling the puzzle

Claudia Pasqualini¹, Mauro Jorini¹, Ines Carloni¹, Mirella Giangiacomi², Valentina Cetica^{3,4}, Maurizio Aricò^{3,4} and Fernando Maria de Benedictis^{1*}

Abstract

Cytophagic histiocytic panniculitis is a rare disease, associated with either nonmalignant conditions or subcutaneous panniculitis-like T-cell lymphoma, and often also associated with hemophagocytic lymphohistiocytosis (HLH). We report the case of a 11-year-old boy with a history of secondary HLH who, after a local trauma, developed a painful, indurated plaque over the right thigh associated with relapsing HLH. Histopathologic findings from skin biopsy specimens revealed significant lobular panniculitis with benign histiocytes showing hemophagocytosis. High-dose intravenous methylprednisolone and cyclosporine A treatment was highly effective. A genetic study after a new, relapsing episode of HLH revealed an heterozygous missense mutation on STX 11 gene inherited from the mother.

Keywords: Panniculitis, Histiocytes, Hemophagocytosis

Background

Cytophagic histiocytic panniculitis (CHP) is a rare disease, first described in 1980, characterized by infiltration of subcutaneous adipose tissue by benign-appearing T lymphocytes and phagocytic histiocytes ("bean bag cells") [1]. CHP may be an isolated skin disease or associated with non-malignant conditions, such as infections, as well as malignancies, including subcutaneous panniculitis-like T-cell lymphoma (SPTL), a rare form of non-Hodgkin lymphoma infiltrating into subcutaneous adipose tissue [2]. Subcutaneous panniculitis has been reported in a small number of patients with hemophagocytic lymphohistiocytosis (HLH), a life threatening condition characterized by uncontrolled activation and proliferation of T-cells resulting in hypercytokinemia, proliferation of histiocytes and hemophagocytosis [3,4]. The familial form of HLH (FHL) is a genetically heterogeneous disorder caused by mutations in genes involved in the granule-dependent exocytosis pathway. Patients with FHL are unable to cope with common pathogens; thus

upon infection with widely diffused agents as cytomegalovirus and Epstein Barr virus, but also less common as leishmania, they develop clinical symptoms and findings of HLH [5]. In order to facilitate the diagnosis of HLH, a set of diagnostic criteria have been developed by the Histiocyte Society [6].

About 40 cases of CHP have been reported so far, mostly in adults [2]. Patients with CHP may have three different clinical courses, mainly depending on isolated presentation or association with HLH. Some patients rapidly progress and often die within one year, due to sepsis, coagulation disorders and multi-organ failure. Others have recurrent bouts of reactivation and may survive for years. Other patients respond well to treatment and may have a normal life [7,8].

We report a severe HLH-associated CHP successfully treated with systemic corticosteroids and cyclosporin A in a child with relapsing HLH and persistent ANA positivity at follow-up.

Case presentation

A previously healthy 11-year-old boy was admitted to our department with persistent fever and increasing dyspnea.

Full list of author information is available at the end of the article

The family history was silent. On admission, the patient had high-grade fever and moderate respiratory distress. Chest examination revealed dullness on percussion and absent breath sound on the right hemithorax. Laboratory tests showed pancytopenia, impaired liver function, raised triglycerides and ferritin levels and low albumin value, without coagulopathy. Anti-nuclear antibodies (ANA) were positive 1:128 with homogeneous pattern. Autoantibody profile (anti-endonuclear, -cardiolipin, -beta2 glycoprotein I, -thyroid, -neutrophil cytoplasm, -mitochondrial and -smooth muscle antibodies) was negative. Blood and urine culture were negative. Virological tests revealed prior/remote Epstein-Barr virus (EBV) infection and negative serology for hepatitis viruses A, B, C, or cytomegalovirus. Chest x-ray showed homogeneous opacity of the right hemithorax. Ultrasound of the chest and abdomen revealed massive pleural effusion, and pericholecystic, perisplenic and perihepatic fluid collection. A chest tube was positioned and a total of 270 ml of cloudy pleural fluid was drained: cytology and biochemical analysis revealed leukocytes 490/mcL (80% lymphocytes), glucose 93 mg/dL, proteins 4,3 gr/dL, lactate dehydrogenase 3948 IU/L; no bacteria were found at the Gram and acid fast bacilli stain; the culture was negative. Bone marrow aspirate showed an increased number of histiocytes phagocytosing red cells and platelets. The number of T, B and NK cells, and granzyme B concentration were within normal ranges. No mutations in *PRF1*, *UNC13D*, *STXBP2*, the genes most frequently associated with familial HLH, were found. HLH secondary to undetermined autoimmune disorder was diagnosed, and treatment with oral dexamethasone (initially 10 mg/m² for 2 weeks followed by 5 mg/m² for 2 weeks, 2.5 mg/m² for 2 weeks, 1.25 mg/m² for one week, and one week of tapering), cyclosporin (6 mg/kg daily) and intravenous etoposide (150 mg/m² twice weekly for 2 weeks and then weekly) was administered for 8 weeks. All symptoms gradually resolved and the patient was maintained on a regular follow-up.

One year later, the child presented with spiking fever and painful swelling of the right thigh which had gradually developed some days after a local trauma. Physical examination revealed a warm, painful, indurated plaque (10x12 cm diameter) over the right thigh. Liver and spleen were mildly enlarged. Routine laboratory tests were non-contributory. ANA were positive 1:1024 with granular pattern. Over a few days, the lesion progressively enlarged and a brownish, hyperpigmented, hyperkeratotic central area appeared (Figure 1). Laboratory tests and bone marrow aspirate were consistent with reactivation of HLH. Skin biopsy revealed a mixed septal and lobular inflammatory infiltrate of benign-appearing histiocytes, plasma cells and lymphocytes, and diffuse fat necrosis (Figure 2a); extensive hemophagocytosis by histiocytic cells was also evident. At the immuno-histochemical staining, nearly all the

Figure 1 Hyperpigmented, indurated plaque with hyperkeratotic central area over the right thigh.

Figure 2 Skin biopsy specimen. **a)** Hematoxylin-eosin stain (4x) showing subcutaneous infiltrate, mainly constituted of mononuclear cells; **b)** Immunohistochemical stain (20x) showing infiltrating histiocytes expressing CD68.

infiltrating lymphocytes expressed the phenotype of cytotoxic T-cell: CD2, CD3, CD5, CD8, but not CD4; CD7 expression was weak to negative; most histiocytes expressed CD68 (Figure 2b). Polymerase chain reaction analysis of the T-cell receptor-gamma chain gene rearrangement confirmed the absence of clonality. Testing for EBV virus by *in situ* hybridization was negative. A diagnosis of HLH-associated CHP was made. High-dose pulse of intravenous methylprednisolone (30 mg/kg/day for 3 days) was started, followed by a combination of dexamethasone (0.25 mg/kg daily) and cyclosporin A (6 mg/kg daily). A dramatic clinical improvement was observed. Dexamethasone was discontinued after 8 weeks, while cyclosporin A was maintained for 12 months.

Six months after discontinuation of cyclosporine A therapy, the patient was admitted for reactivation of HLH (Table 1). Thus, a more extensive genetic study for familial HLH was performed. Mutation analysis revealed heterozygous missense mutation (c.991G > A p.V267M) in the *STX11* gene. In silico analysis performed using the web query tools (Pmut, Polyphen, SIFT) confirmed that this mutation is not tolerated. Combined treatment with steroids (high-dose pulse of intravenous methylprednisolone 30 mg/kg/day for 3 days, followed by dexamethasone 0.10 mg/kg daily) and cyclosporine A (5 mg/kg daily) was reinstated for 6 weeks and 12 months, respectively. Clinical and laboratory remission was sustained at 6 month follow-up. Over the years, ANA title remained persistently positive 1:256 to 1:1024 with granular pattern.

Conclusions

Our case is worthy of description for several reasons. First, there is no mention in the literature of autoimmune involvement in patients with CHP. ANA were positive at the

presentation of HLH and their values remained persistently high over the years. The meaning of ANA positivity in the picture of systemic disease remains intriguing. Ravelli et al. [9] suggested that ANA positivity is the hallmark of a specific subset of patients with juvenile idiopathic arthritis which should be classified separately for their different prognosis [10]. Whether persistent ANA positivity in our patient may represent a different setting of the immune system cannot be defined at present. Furthermore, a local trauma was revealed some days before panniculitis was evident. To our knowledge, this finding has not been reported in CHP and trauma might act as precipitating factor.

The spectrum of mutations involved in FHL has expanded since the original report of perforin defect in 1999, with mutations identified in the *UNC13D* (FHL3), *STX11* (FHL4) and *STXBP2* (FHL5) genes [11]. While original reports of FHL4 were restricted to families of Turkish/Kurdish origin, patients of different origins have been recently identified with defect in *STX11* [11,12]. The relevance of cooperation between the syntaxins and other proteins involved in the degranulation machinery is being progressively elucidated [13]. Recent studies in patients with FHL suggested that monoallelic mutation in FHL-related genes may behave as predisposing factor for several human disorders [14-16]. The working hypothesis is that partial impairment of the cellular cytotoxicity machinery may predispose, or contribute, to several disorders in which the immune system plays a significant role [11,12]. Our patient bears a monoallelic, novel *STX11* mutation, which was predicted to be pathogenic by in silico analysis.

Once CHP is suspected, the diagnosis relies mainly on histopathology findings. In such context, discriminating between CHP and SPTL is therapeutically important because nonmalignant CHP often improves under pulses of high-

Table 1 Clinical features and laboratory findings at first admission and at relapses

	1st admission	1st relapse	2nd relapse
<i>Clinical features</i>	Spiking fever	Spiking fever	Fever
	Respiratory distress	Swelling of the right thigh	Cough
	Absent breath sound on right hemithorax	Liver and spleen enlargement	
<i>Laboratory findings</i>

dose intravenous methylprednisolone and cyclosporine A [17], whereas most cases of SPTL may be best treated with more aggressive therapy. Marzano et al. [18] suggested that these conditions might span a clinical-pathological spectrum in which there is a natural progression from CHP to SPTL. Since the distinction of CHP from SPTL is difficult and CHP might be a precursor of SPTL [19], some authors proposed to use the term “panniculitis-like subcutaneous lymphoma with cytophagocytosis” instead of CHP, even when T-cell clonality was not documented [20]. This approach would have a beneficial effect on treatment planning towards oncological rather than anti-inflammatory therapy. Bader-Meunier et al. [21] recently emphasized that HLH-associated CHP may be diagnosed despite monoclonal T-cell proliferation that mimics SPTL and is best treated by prednisone and cyclosporine A, at least in children. It has been suggested that this florid clonal T-cell proliferation is reactive, probably driven by a strong immune reaction against EBV infection [22]. Furthermore, Huppmann et al. [23] confirmed that molecular studies are diagnostically helpful but not specific, since the absence of clonality does not rule out the diagnosis of SPTL.

The diagnosis of CHP is challenging, but it was supported by several data in our case. Although many histopathology findings are common to both CHP and SPTL, rimming of the fat vacuoles by atypical lymphoid cells is a useful diagnostic feature for SPTL [24]. Furthermore, the development of HLH is extremely rare, has an aggressive course and is typically associated with a poor outcome in children with SPTL [25]. In our patient, the rimming pattern was absent in the skin infiltrate and the outcome of HLH was favourable.

Another entity within the differential diagnosis spectrum of lobular panniculitis is lupus erythematosus panniculitis (LEP) [26], a rare variant of lupus erythematosus which can present as an isolated phenomenon and is most commonly localized to upper arm. The presence of HLH in LEP, has been rarely described [27]. Male gender, involvement of the thigh, good response to therapy, lack of relapse after treatment discontinuation, and absence of characteristic histopathology findings of lupus erythematosus supported the diagnosis of CHP.

The remission of the symptoms of CHP and HLH under the association of high-dose intravenous methylprednisolone and cyclosporine A in our patient supports that this combination is the treatment of choice for nonmalignant CHP associated with HLH. Cytotoxic chemotherapy should be considered for relapsing/refractory disease or more severe forms [28]. High-dose chemotherapy followed by autologous peripheral blood stem cell transplantation may be necessary for the treatment of particularly aggressive CHP [29].

The small number of reported patients with HLH-associated CHP does not permit to hypothesize any factor that may predict the clinical course or guide the optimal treatment. Searching for biological features such as underlying genetic mutations may help to better understand the variability of the clinical course and the response to treatment. Prompt diagnosis of CHP and HLH, close cooperation between rheumatologists, hematologists, dermatologists and pathologists, and continued follow up remain an imperative matter that can make the difference between life and death.

Consent

Written informed consent was obtained from the parents of the patient for publication of this Case Report and any accompanying images. A copy of written consent is available for review by the editor-in-chief of this journal.

Abbreviations

CHP: Cytophagic histiocytic panniculitis; SPTL: Subcutaneous panniculitis-like T-cell lymphoma; HLH: Hemophagocytic lymphohistiocytosis; LEP: Lupus erythematosus panniculitis.

Competing interests

The authors declare that they have no competing interests.

Authors' contributions

CP identified the case, helped in making the diagnosis and worked on bibliography. MJ was involved in the diagnostic process, therapeutic decisions and follow up. IC drafted the manuscript. MG made substantial contribution to analysis and interpretation of immunohistochemical data. VC performed mutation analysis. MA supervised mutation analysis and revised the manuscript. FMD supervised the diagnostic and therapeutic approach, and critically revised the manuscript. All authors read and approved the final manuscript.
